The characterization of an infinite-order quantum phase transition (QPT) by entanglement measures is analyzed. To this aim, we consider two closely related solvable spin-1/2 chains, namely, the Ashkin-Teller and the staggered XXZ models. These systems display a distinct pattern of eigenstates but exhibit the same thermodynamics, i.e. the same energy spectrum. By performing exact diagonalization, we investigate the behavior of pairwise and block entanglement in the ground state of both models. In contrast with the XXZ chain, we show that pairwise entanglement fails in the characterization of the infinite-order QPT in the Ashkin-Teller model, although it can be achieved by analyzing the distance of the pair state from the separability boundary. Concerning block entanglement, we show that both XXZ and Ashkin-Teller models exhibit identical von Neumann entropies as long as a suitable choice of blocks is performed. Entanglement entropy is then shown to be able to identify the quantum phase diagram, even though its local extremes (either maximum or minimum) may also appear in the absence of any infinite-order QPT.

I. INTRODUCTION

The behavior of entanglement in many-body systems has attracted great attention in recent years due to its promising potential to realizing quantum information tasks [1–3] as well as its relationship with quantum critical phenomena [4]. In particular, it has been observed that entanglement can identify and characterize a quantum phase transition (QPT) [5, 6]. QPTs are associated with critical changes in the ground state of a quantum system due to level crossings in its energy spectrum, occurring at low temperatures T (effectively $T = 0$). Specifically, a first-order QPT is characterized by a finite discontinuity in the first derivative of the ground state energy. Similarly, a second-order QPT – or a continuous QPT – is characterized by the existence of an infinite correlation length and a power-decay of correlations, which is often manifested by a finite discontinuity or divergence in the second derivative of the ground state energy, assuming the first derivative is continuous. A more subtle class is the so-called infinite-order QPTs, for which any finite-order derivative of the ground state energy is a continuous function of the relevant parameters. Prominent examples of such QPTs are provided by the metal-insulator point in the fermionic Hubbard model and the SU(2) (antiferromagnetic) Heisenberg point in the XXZ spin-1/2 chain.

In recent years, it has been noticed that the behavior of entanglement (or its derivatives) in the ground state of a many-body system undergoing a first-order or a continuous QPT exhibits a non-analyticity. Indeed, in the case of first-order QPTs, discontinuities in the ground

state entanglement were shown to detect the QPT [7–9]. For the case of second-order QPTs, the critical point is found to be associated with a singularity in the derivative of the ground state entanglement, as first illustrated for the transverse field Ising chain in Ref. [4], and generalized in Refs. [10–12] (see also Refs. [13–17] for an analysis in terms of other entanglement measures). The behavior of entanglement for first-order and second-order QPTs have also been discussed in general grounds in Refs. [18, 19]. For infinite-order QPTs, although no independent-model analysis is available, entanglement has been found to exhibit a local extreme (either maximum or minimum) at the quantum critical point (QCP). This has indeed been shown for the spin-1/2 XXZ chain [20–23] and for the fermionic Hubbard model [24]. Whether or not this is a general property of an entanglement measure for a convenient partition of the system remains unresolved.

In order to make progress on this matter and on the general properties of an infinite-order QPT, we will consider in this paper the characterization of entanglement into two closely related solvable spin-1/2 chains, namely, the Ashkin-Teller and the staggered XXZ models. The Ashkin-Teller model has been introduced as a generalization of the Ising spin-1/2 model to investigate the statistics of two-dimensional lattices with four-state interacting sites [31]. Since then, it has attracted a great deal of attention due to its motivations in a wide range of research fields. First, both its classical and quantum versions exhibit a rich phase diagram [32, 33], which makes the model a prototype for the investigation of phase transitions and critical phenomena. For instance, it has recently been shown that the quantum Ashkin-Teller model in one-dimension exhibits an example of disorder rounding of a first order quantum phase transition into a continuous phase transition [34], which may find applications to numerous complex strongly correlated systems. Second, it has been experimentally

*Electronic address: rulli@if.uff.br

†Electronic address: msarandy@if.uff.br

realized by magnetic compounds formed by layers of atoms adsorbed on clean surfaces, e.g., Selenium adsorbed on Ni(100) surface [35]. Moreover, the universality properties Ashkin-Teller model may also be related to many other interesting applications, such as nonabelian anyons models [36], orbital current loops in CuO₂-plaquettes of high-T_c cuprates [37], and elastic response of DNA molecules [38]. Remarkably, the Ashkin-Teller model and the XXZ chain display a distinct pattern of eigenstates but exhibit the same thermodynamics, i.e. the same energy spectrum. In particular, the same quantum phase diagram applies to both models, although entanglement can be distinct in each case. Our aim is then analyze this quantum phase diagram and investigate to what extent entanglement measures will agree on the description of the infinite-order QCP. Indeed, as we will see, in contrast with the XXZ chain, pairwise entanglement between nearest neighbors in the Ashkin-Teller model is not able to identify the QPT. By focusing on block entanglement, we will then show how to reconcile the behavior of entanglement in both cases. Moreover, we will show that local extremes may also occur in the absence of any infinite-order QPT, indicating that further analysis of the critical behavior is demanded in a scenario where entanglement displays a local maximum or minimum driven by a relevant parameter.

II. THE ASHKIN-TELLER MODEL AND ITS MAP INTO THE STAGGERED XXZ CHAIN

Let us begin by introducing the quantum Ashkin-Teller model in one-dimension, whose Hamiltonian for a chain with M sites is given by

$$H_{AT} = -J \sum_{j=1}^M (\sigma_j^x + \tau_j^x + \Delta \sigma_j^x \tau_j^x) - J\beta \sum_{j=1}^M (\sigma_j^z \sigma_{j+1}^z + \tau_j^z \tau_{j+1}^z + \Delta \sigma_j^z \sigma_{j+1}^z \tau_j^z \tau_{j+1}^z), \quad (1)$$

where σ_j^α and τ_j^α ($\alpha = x, y, z$) are independent Pauli spin-1/2 operators, J is the exchange coupling constant, Δ and β are (dimensionless) parameters, and periodic boundary conditions (PBC) are adopted, i.e., $\sigma_{M+1}^\alpha = \sigma_1^\alpha$ and $\tau_{M+1}^\alpha = \tau_1^\alpha$ ($\alpha = x, y, z$). The Ashkin-Teller model is $Z_2 \otimes Z_2$ symmetric, with the Hamiltonian commuting with the parity operators

$$\mathcal{P}_1 = \prod_{j=1}^M \sigma_j^x \quad \text{and} \quad \mathcal{P}_2 = \prod_{j=1}^M \tau_j^x. \quad (2)$$

Therefore, the eigenspace of H_{AT} can be decomposed into four disjoint sectors labelled by the eigenvalues of $\mathcal{P}_1$ and $\mathcal{P}_2$, namely, $Q = 0$ ($\mathcal{P}_1 = +1, \mathcal{P}_2 = +1$), $Q = 1$ ($\mathcal{P}_1 = +1, \mathcal{P}_2 = -1$), $Q = 2$ ($\mathcal{P}_1 = -1, \mathcal{P}_2 = -1$), and $Q = 3$ ($\mathcal{P}_1 = -1, \mathcal{P}_2 = +1$). By the symmetry of H_{AT}

under the interchange $\sigma^\alpha \leftrightarrow \tau^\alpha$, the sectors $Q = 1$ and $Q = 3$ are degenerate. Moreover, we observe that the ground state belongs to the sector $Q = 0$.

In order to map the Ashkin-Teller model into the staggered XXZ chain, we consider two sets of $2M$ link variables $\{\eta_j, \gamma_j | j = 1, \dots, 2M\}$, which are defined by

$$\begin{aligned} \eta_{2j-1} &= \sigma_j^x, & \gamma_{2j-1} &= \tau_j^x, \\ \eta_{2j} &= \sigma_j^z \sigma_{j+1}^z, & \gamma_{2j} &= \tau_j^z \tau_{j+1}^z. \end{aligned} \quad (3)$$

These variables satisfy the conditions

$$\eta_j^2 = \mathbb{1}, \quad \gamma_j^2 = \mathbb{1} \quad (j = 1, \dots, 2M). \quad (4)$$

Moreover, they obey the algebra

$$[\eta_j, \gamma_k] = 0, \quad [\eta_j, \eta_k] = 0, \quad [\gamma_j, \gamma_k] = 0, \quad (5)$$

for $|j - k| \neq 1$ and $(j, k) \neq (1, 2M)$ and $(j, k) \neq (2M, 1)$, while

$$[\eta_j, \gamma_k] = 0, \quad \{\eta_j, \eta_k\} = 0, \quad \{\gamma_j, \gamma_k\} = 0, \quad (6)$$

for $|j - k| = 1$ or $(j, k) = (1, 2M)$ or $(j, k) = (2M, 1)$. However, note that, since PBC are adopted, the link variables are not completely independent, turning out to obey the constraints

$$\prod_{j=1}^M \eta_{2j} = \prod_{j=1}^M \gamma_{2j} = \mathbb{1}. \quad (7)$$

Moreover, by writing out H_{AT} in terms of the link variables, we obtain

$$\begin{aligned} H_{AT} &= - \sum_{j=1}^{2M} J (\eta_{2j-1} + \gamma_{2j-1} + \Delta \eta_{2j-1} \gamma_{2j-1}) \\ &\quad - J\beta \sum_{j=1}^{2M} (\eta_{2j} + \gamma_{2j} + \Delta \eta_{2j} \gamma_{2j}). \end{aligned} \quad (8)$$

The equivalence between the Ashkin-Teller model and the XXZ chain can be established by considering the staggered spin-1/2 XXZ chain with $2M$ sites, whose Hamiltonian reads

$$\begin{aligned} H_{XXZ} &= - \sum_{j=1}^M J [\sigma_{2j-1}^x \sigma_{2j}^x + \sigma_{2j-1}^y \sigma_{2j}^y - \Delta \sigma_{2j-1}^z \sigma_{2j}^z] \\ &\quad - J\beta \sum_{j=1}^M [\sigma_{2j}^x \sigma_{2j+1}^x + \sigma_{2j}^y \sigma_{2j+1}^y - \Delta \sigma_{2j}^z \sigma_{2j+1}^z], \end{aligned} \quad (9)$$

where, as before, J is the exchange coupling constant, Δ and β are the anisotropy and staggering (dimensionless) parameters, respectively, and PBC are adopted, i.e., $\sigma_{2M+1}^\alpha = \sigma_1^\alpha$ ($\alpha = x, y, z$). Note that, differently from the Ashkin-Teller model, the XXZ chain has one spin-1/2 particle *per* site. The XXZ model is U(1) invariant, with

the Hamiltonian commuting with the total spin operator $S^z = \sum_{j=1}^{2M} \sigma_j^z$, i.e.,

$$[H_{XXZ}, S^z] = 0. \quad (10)$$

Therefore, the eigenspace of H_{XXZ} can be decomposed into $2M+1$ disjoint sectors labelled by their corresponding magnetization quantum number $n = M - r$, with $r = 0, 1, \dots, 2M$ denoting the number of spins reversed from the state with all spins down. We observe that the ground state belongs to the sector $n = 0$. A schematic view of the XXZ and Ashkin-Teller chains is shown in Fig. 1.

FIG. 1: (Color online) (a) Ashkin-Teller spin-1/2 chain. The lattice is composed by two independent spin-1/2 particles *per* site j described by Pauli operators $\{\sigma_j^\alpha, \tau_j^\alpha\}$. (b) XXZ spin-1/2 chain. The lattice is composed by one spin-1/2 particle *per* site j described by Pauli operators $\{\sigma_j^\alpha\}$.

As defined for the Ashkin-Teller model, we introduce two sets of link variables, $\{\eta_j, \gamma_j | j = 1, \dots, 2M\}$, which are given by

$$\begin{aligned} \eta_{2j-1} &= \sigma_{2j-1}^x \sigma_{2j}^x, & \gamma_{2j-1} &= \sigma_{2j-1}^y \sigma_{2j}^y, \\ \eta_{2j} &= \sigma_{2j}^y \sigma_{2j+1}^y, & \gamma_{2j} &= \sigma_{2j}^x \sigma_{2j+1}^x, \end{aligned} \quad (11)$$

with $j = 1, \dots, M$. These variables also satisfy the conditions given by Eq. (4) and the algebra given by Eqs. (5) and (6). Moreover, we observe that the constraints obeyed now by the link variables with PBC adopted read

$$\prod_{j=1}^M \eta_{2j-1} \gamma_{2j} = \prod_{j=1}^M \gamma_{2j-1} \eta_{2j} = \mathbb{1}. \quad (12)$$

By writing H_{XXZ} in terms of $\{\eta_j, \gamma_j\}$ we obtain the same expression as in Eq. (8). Therefore, an equivalence between H_{XXZ} and H_{AT} can be achieved as long as the constraints given by Eqs. (7) and (12) can be made compatible between each other. In this direction, we can show that, despite displaying rather different ground state vectors, the XXZ and Ashkin-Teller models, as defined by Eqs. (9) and (1), exhibit the same ground state energy. More specifically, with PBC adopted, it can be shown [25] that the energies in the sector $Q = 0$ of H_{AT} , which contains the ground state, will occur in the spectrum of H_{XXZ} . Indeed, observe first that eigenstates of H_{AT} into the sector $Q = 0$ are characterized by

$$\prod_{j=1}^M \sigma_j^x = \mathbb{1}, \quad \prod_{j=1}^M \tau_j^x = \mathbb{1}, \quad (13)$$

which is a consequence of Eq. (2). Then, by inserting Eq. (13) into Eq. (7), we exactly obtain the constraint given by Eq. (12). Therefore, all the energy levels belonging to $Q = 0$ also appear in H_{XXZ} . Conversely, we can show here that the ground state energy of the XXZ model is also contained into the spectrum of H_{AT} . Indeed, besides the $U(1)$ symmetry given by Eq. (10), H_{XXZ} is also invariant under $Z(2)$ transformations, namely, it commutes with the parity operators

$$Q_\alpha = \prod_{j=1}^{2M} \sigma_j^\alpha, \quad (14)$$

with $\alpha = x, y, z$. In particular, the ground state of H_{XXZ} is into the sector of eigenstates $\{|\psi\rangle\}$ such that

$$Q_x |\psi\rangle = +|\psi\rangle, \quad Q_y |\psi\rangle = +|\psi\rangle. \quad (15)$$

Then, by using Eq. (15) into Eq. (12), we exactly obtain the constraint given by Eq. (7). Therefore, all the energy levels belonging to the sector $Q_x = +1, Q_y = +1$ also appear in H_{AT} . Hence, we can conclude that the ground state energy $E_0(\Delta, \beta)$ of both models are identical for any Δ and β . Remarkably, this equivalence can be extended to the whole spectrum if open ends are adopted [25]. Bearing in mind that H_{XXZ} and H_{AT} have the same ground state energy, they will manifest the same quantum phase diagram as the anisotropy Δ and the staggering parameter β are varied. Naturally, the character of the quantum phase itself depends on the particular model, since it is associated with the properties of the ground state vector. The quantum phase

FIG. 2: (Color online) Quantum phase diagram of Ashkin-Teller and staggered XXZ models. The energy scale J is set to one.

diagram for H_{AT} and H_{XXZ} is sketched in Fig. 2. The quantum phases for the Ashkin-Teller model can be described as the following: the ferromagnetic phase (F), where $\langle \sigma_j^z \rangle = \langle \tau_j^z \rangle \neq 0$, the paramagnetic phase (P), where $\langle \sigma_j^z \rangle = \langle \tau_j^z \rangle = 0$, and the partially ordered phase (G), where $\langle \sigma_j^z \tau_j^z \rangle \neq 0$. Since our main focus is the investigation of the infinite-order point $\beta = 1$ and $\Delta = 1$, we will concentrate on the diagram starting on point

$\Delta = -\sqrt{2}/2$, where we have the beginning of a critical line of continuous QPTs.

III. PAIRWISE ENTANGLEMENT

Let us first analyze the behavior of entanglement for pairs of spins in the XXZ and Ashkin-Teller models. To this aim, we quantify entanglement by employing the negativity [26, 27], which is given by

$$\mathcal{N}(\rho^{ij}) = 2 \max(0, -\min_{\alpha}(\lambda_{\alpha}^{ij})), \quad (16)$$

where λ_{α}^{ij} are the eigenvalues of the partial transpose $\rho^{ij,TA}$ of the two-spin density operator ρ^{ij} , defined as $\langle \alpha\beta | \rho^{TA} | \gamma\delta \rangle = \langle \gamma\beta | \rho | \alpha\delta \rangle$. For the (non-staggered) XXZ model, pairwise entanglement between nearest-neighbors in the ground state of the chain has been evaluated in several previous works [20–23], with entanglement measured either by negativity or concurrence [28]. For the specific case of ground state entanglement in the XXZ model, negativity and concurrence turn out to be identical [23, 29]. In particular, at the infinite-order QCP $\Delta = 1$, it has been shown that the negativity achieves a maximum given by 0.386. Indeed, this maximum is rather robust, appearing not only in the ground state but also for all conformal towers associated with H_{XXZ} formed by an infinite number of excited states [23].

Concerning the Ashkin-Teller model, we have two different spins at each site, given by the Pauli operators σ and τ . We will consider here entanglement between pairs $\sigma_j - \tau_{j+1}$, $\sigma_j - \sigma_{j+1}$, and $\tau_j - \tau_{j+1}$ at nearest neighbour sites as well as pairs $\sigma_j - \tau_j$ at the same site (frontal pairs). Since the Hamiltonian is symmetric by an interchange $\sigma \leftrightarrow \tau$, both $\sigma_j - \sigma_{j+1}$ and $\tau_j - \tau_{j+1}$ exhibit the same entanglement properties. The negativity for these pairs is rather different of that for nearest neighbor spins in the XXZ chain, displaying no signature (e.g., a maximum) of the infinite-order QPT. This result is plotted in Fig. 3(a). For the spins $\sigma_j - \tau_j$ and $\sigma_j - \tau_{j+1}$, we can show that the negativity is vanishing for any Δ , as given by Figs. 3(b) and 3(c). Therefore, entanglement for these pairs do not exhibit any indication of the quantum critical behavior. However, an indication of the infinite-order QPT can be obtained by looking at a closely related quantity, which is the distance of the separability boundary (DSB), denoted by $\Lambda(\rho^{ij})$. By following Ref. [30], we can define $\Lambda(\rho^{ij})$ from Eq. (16) through

$$\Lambda(\rho^{ij}) = -2 \min_{\alpha}(\lambda_{\alpha}^{ij}). \quad (17)$$

Note that $\Lambda > 0$ implies an entangled state with $\Lambda(\rho^{ij}) = \mathcal{N}(\rho^{ij})$. It can be shown that $\Lambda = 0$ for *pure* separable states while $\Lambda < 0$ for *mixed* separable states. Results for Λ in a chain with 20 spins are shown in Fig. 3(a), 3(b), and 3(c). Note that the distance Λ for the frontal pair of spins presents a cusp at the infinite-order QCP. This cusp is actually hidden by the max operation and is kept

FIG. 3: (Color online) Negativity $\mathcal{N}$ (solid black line) and DSB Λ for the pairs (a) $\sigma_j - \sigma_{j+1}$ and $\tau_j - \tau_{j+1}$, (b) $\sigma_j - \tau_{j+1}$, and (c) $\sigma_j - \tau_j$ in the Ashkin-Teller chain with 20 spins. Note that the only nearest spin pairs with nonvanishing entanglement are given by curve (a). The results are plotted for $\beta = 1$.

FIG. 4: (Color online) Negativity $\mathcal{N}$ (solid black line) and DSB Λ for a frontal pair $\sigma_j - \tau_j$ for chains with 6, 8, and 20 spins (from top to bottom) as a function of Δ . Note that the operation max hides the nonanalyticity exhibited by Λ . The results are plotted for $\beta = 1$.

unchanged for larger chains, as shown in Fig. 4. In order to understand the nonanalyticity of Λ in $\Delta = 1$, let us consider the density matrix for $\sigma_j - \tau_j$, which is given by

$$\rho^{j,j} = \begin{pmatrix} u(\Delta) & 0 & 0 & 0 \\ 0 & v(\Delta) & 0 & 0 \\ 0 & 0 & v(\Delta) & 0 \\ 0 & 0 & 0 & w(\Delta) \end{pmatrix}, \quad (18)$$

where $u(\Delta) = \frac{1}{4} + \frac{1}{2}m(\Delta) + \frac{1}{4}G(\Delta)$, $v(\Delta) = \frac{1}{4} - \frac{1}{4}G(\Delta)$, and $w(\Delta) = \frac{1}{4} - \frac{1}{2}m(\Delta) + \frac{1}{4}G(\Delta)$, with $m(\Delta)$ denoting the magnetization density in the x direction, namely, $m(\Delta) = \langle \sigma_k^x \rangle = \langle \tau_k^x \rangle$ and $G(\Delta) = \langle \sigma_k^x \tau_k^x \rangle$. Since the density matrix is diagonal, the partial transposition keeps the same eigenvalues as $\rho^{j,j}$. Then, it can be numerically

shown that the DSB reads

$$\Lambda = \begin{cases} -\frac{1}{2} + m(\Delta) - \frac{1}{2}G(\Delta) & \text{if } \Delta \leq 1, \\ -\frac{1}{2} + \frac{1}{2}G(\Delta) & \text{if } \Delta > 1. \end{cases} \quad (19)$$

Therefore, there is a change in the behavior of Λ exactly at $\Delta = 1$, which makes the DSB a useful pairwise quantity capable of identifying the infinite-order QCP in the Ashkin-Teller model.

IV. BLOCK ENTANGLEMENT

As we have seen, in contrast with the XXZ model, pairwise entanglement alone (with no DSB supplementary analysis) fails to identify the infinite-order QCP in the Ashkin-Teller model. In this section, we will show that bipartite block entanglement as measured by the von Neumann entropy is able to provide a unique description of entanglement for both the XXZ and Ashkin-Teller models. Given a quantum system in a pure state $|\psi\rangle$ and a bipartition of the system into two blocks A and B , entanglement between A and B can be measured by the von Neumann entropy S of the reduced density matrix of either of blocks, i.e.,

$$S = -\text{Tr}(\rho_A \log_2 \rho_A) = -\text{Tr}(\rho_B \log_2 \rho_B), \quad (20)$$

where $\rho_A = \text{Tr}_B \rho$ and $\rho_B = \text{Tr}_A \rho$ denote the reduced density matrices of blocks A and B , respectively, with $\rho = |\psi\rangle\langle\psi|$.

Concerning the XXZ model, it has been shown that local extremes of the von Neumann entropy are able to identify the quantum phase diagram [21]. In the case of the Ashkin-Teller model, we will show here that the entanglement entropy can also identify the infinite-order QPT by a local extreme, displaying a superior behavior in comparison with pairwise entanglement. Moreover, for a suitable choice of blocks, we can also show that the entanglement entropy is the same as that of the XXZ model. Indeed, a sublattice composed by a *contiguous* block of spins in the XXZ chain will exhibit the same von Neumann entropy as a set of *contiguous* frontal pairs of spins in the Ashkin-Teller model. This is analytically worked out in the Appendix for a two-spin block and numerically checked for larger blocks. The map of equivalent entropies is sketched in Fig. 5.

FIG. 5: (Color online) Map of spins to obtain the equivalence of the entanglement entropies for the Ashkin-Teller and XXZ models.

Note that the map above refers to the von Neumann entropy only. Naturally, it is not applicable to obtain equivalences in the case of other physical quantities, e.g.,

pairwise entanglement. As we have seen, no equivalence can be obtained in that case. In order to investigate the characterization of the QPT by using bipartite block entanglement, let us first consider the situation $\beta = 1$ (non-staggered model). Then, by performing exact diagonalization, we plot in Fig. 6 the von Neumann entropy $S(\Delta)$ for a single frontal pair of spins in a chain with different lengths as a function of the anisotropy Δ . Note that, independently of the chain size, $S(\Delta)$ presents a maximum exactly at $\Delta = 1$ (see Inset). We can also show that the maximum at the critical point is robust against the increase of the size of the blocks as well as the choice of the sublattices. This is particularly shown in Fig. 7, where it is exhibited the entropy in the Ashkin-Teller model for different choices of sublattices in a chain with 20 spins. Note that the entropy gets larger as we increase the number of bonds between the sublattices, i.e., $S(\Delta)$ increases according to the direction *red* [curve (a)] to *blue* [curve (c)] of Fig. 7. Again, a maximum is observed at $\Delta = 1$ (see inset). As mentioned before, entanglement in the Ashkin-Teller model will match entanglement in the XXZ chain for contiguous blocks of spins (e.g., the *red* plot [curve (a)] of Fig. 7).

FIG. 6: (Color online) Block entanglement $S(\Delta)$ as a function of the anisotropy Δ for a single frontal pair of spins. From bottom to top, the chain lengths are 6, 8, 10, 12, 14, and 20 spins, respectively. Inset: the derivatives of $S(\Delta)$ vanish at $\Delta = 1$.

Hence, the von Neumann entropy provides a completely equivalent description of block entanglement in the XXZ and Ashkin-Teller models, being able to characterize the QPT by a maximum at $\Delta = 1$. We shall now analyze the case of staggering parameters $\beta \neq 1$. Let us consider the entanglement between a frontal pair and all the rest of the chain in the Ashkin-Teller model. The resulting entropy for a chain with 20 spins is plotted in Fig. 8 as a function of Δ for several values of the staggering parameter β .

Note that for $\beta \geq 1$ the von Neumann entropy displays a maximum at $\Delta = 1$ while for $\beta < 1$ it is characterized by a minimum at $\Delta = 1$. The change in the concavity of $S(\Delta)$ at $\beta = 1$ is rather robust, being independent of the size of the chain. However, by looking at

FIG. 7: (Color online) Block entanglement $S(\Delta)$ as a function of the anisotropy Δ for $L = 4$ sites in different configurations in a chain with $N = 20$ spins. Inset: derivatives of $S(\Delta)$, all of them vanishing at $\Delta = 1$.

FIG. 8: (Color online) Entanglement entropy for a frontal pair $\sigma_j - \tau_j$ in the Ashkin-Teller chain with 20 spins as a function of Δ for different values of the staggering couplings β . From bottom to top, the figures are plotted for $\beta = \frac{1}{2}, \frac{3}{4}, 1, \frac{5}{4}$, and $\frac{7}{4}$, respectively. Inset: the derivatives of $S(\Delta)$ vanish at $\Delta = 1$ and indicate a pronounced maximum (or minimum) around the second-order QPT.

the quantum phase diagram at Fig. 2, we can see that, for $\beta \neq 1$, there is no infinite-order QPT at $\Delta = 1$. Therefore, we are providing here an example of a local extreme of entanglement that is not associated with a QPT. Nontrivial staggering is then able to introduce a phenomenon that is absent in the standard case. Nevertheless, observe that the concavity of the curve can characterize the paramagnetic-ferromagnetic QPT, namely, the von Neumann entropy always displays a maximum at the ferromagnetic (F) case while a minimum is found in the paramagnetic (P) region. Therefore, the concavity of $S(\Delta)$ provides a necessary condition (that is also sufficient for $\Delta \leq 1$) to determine the phases F and P. Moreover, note that entanglement also detects both the P-G and F-G QPTs of Fig. 2, given by horizontal cross-

ings at the phase diagram for a fixed β . Indeed, these P-G and F-G crossings are second-order QPTs, with the first derivative of entanglement getting a pronounced maximum (or minimum) at the QPT. This is exhibited in the Inset of Fig. 8. The behavior above is also kept if we increase the size of the block. Indeed, we plot in Fig. 9 the entanglement between a quartet composed by two frontal spins and all the rest of the chain, which exhibits the same pattern of maxima and minima for the entropy as in the case of single frontal spin pairs.

FIG. 9: (Color online) Entanglement entropy for a quartet in the Ashkin-Teller chain with 20 spins as a function of Δ for different values of the staggering couplings β . From bottom to top, the figures are plotted for $\beta = \frac{1}{2}, \frac{3}{4}, 1, \frac{5}{4}$, and $\frac{7}{4}$, respectively. Inset: the derivatives of $S(\Delta)$ vanish at $\Delta = 1$ and indicate a pronounced maximum (or minimum) around the second-order QPT. These maxima are expected to scale as we increase the size of the chain.

We observe that the pronunciation of the maximum or the minimum of the derivative of entanglement at a second-order QPT is expected to evolve to a nonanalyticity as we increase the size of the chain [18, 19]. This is indicated in Fig. 10, where the entropy as a function of β reveals the second-order QPTs by vertical crossings at the phase diagram given by Fig. 2 for a fixed Δ .

Note from Fig. 10 that, for any size of the chain, entanglement entropy for a quartet tends to 2 as $\beta \rightarrow \infty$. This can be understood as a consequence of the map shown in Fig. 5, where we replace the entropy of the quartet by the entropy of four contiguous spins in the XXZ chain. Indeed, in the limit $\beta \rightarrow \infty$, the ground state of the Hamiltonian (9) is given by a set decoupled dimers, whose density operator is $\rho = \rho_{2,3} \otimes \rho_{4,5} \otimes \dots \otimes \rho_{2M,1}$, with $\rho_{2j,2j+1} = (1/4)(\mathbb{1}_{2j} \otimes \mathbb{1}_{2j+1} + \sigma_{2j}^x \otimes \sigma_{2j+1}^x + \sigma_{2j}^y \otimes \sigma_{2j+1}^y - \sigma_{2j}^z \otimes \sigma_{2j+1}^z)$. With no loss of generality, by analyzing the quartet $\rho_{1,2,3,4}$, we obtain that $\rho_{1,2,3,4} = (1/4)(\mathbb{1}_1 \otimes \rho_{2,3} \otimes \mathbb{1}_4)$. Then it follows that $S(\rho_{1,2,3,4}) = 2$, which comes from the contribution of the spin singlets $(2M, 1)$ and $(4, 5)$.

FIG. 10: (Color online) Entanglement entropy for a quartet in the Ashkin-Teller chain with 8 (dashed red curve) and 20 spins (solid black curve) as a function of β for $\Delta = 5$. Inset: the first derivative of $S(\beta)$ displays pronounced maxima at $\beta \approx 0.337$ and $\beta \approx 2.14$, which are finite-size precursors of the second-order QPTs. These maxima are expected to scale as we increase the size of the chain.

V. CONCLUSIONS

In summary, we have presented a detailed analysis of entanglement into two closely related models, namely, the staggered XXZ and Ashkin-Teller models. In particular, the behavior of the entanglement properties in both models has been considered at the infinite-order QCP, where we have shown that pairwise entanglement in the Ashkin-Teller model fails in the characterization of the QPT (with no DSB supplementary analysis). However, the von Neumann entropy can offer a unified description of quantum criticality, with this equivalence achieved for contiguous blocks of spins. Moreover, we have also shown that the pattern of local extremes at the infinite-order QCP has been obtained by using bipartite block entropy for different choices of sublattices, even though local extremes also appear in regions where no QPTs occur. This result establishes that the maxima and minima of entanglement entropy *per se* constitute, in the absence of supplementary analysis, *insufficient* conditions to ensure the existence of an infinite-order QPT.

The local extremes pattern of entanglement for infinite-order QPTs has been observed for a variety of different systems, despite no analytical derivation of this behavior is available. This is in contrast with first-order and continuous QPTs, where the relationship between QPTs and nonanalytical behavior of entanglement has been generically understood for finite dimensional bipartite [18] and multipartite [39] systems as well as for con-

tinuous variable models [40]. We have provided here new indications that local extremes provide a typical but not sufficient characterization of infinite-order QPTs, which may provide a hint for a future derivation of this phenomenon in general grounds.

Appendix

Let us show in this appendix that the reduced density operator ρ_j^{AT} for a frontal spin pair at site j in the Ashkin-Teller is equivalent to a nearest-neighbor two-spin reduced density operator $\rho_{j,j+1}^{XXZ}$ in the XXZ chain. Starting from the Ashkin-Teller model, ρ^{AT} reads

$$\rho_j^{AT} = \frac{1}{4} (\mathbb{1}_4 + u \sigma_j^x + u \tau_j^x + v \sigma_j^x \tau_j^x), \quad (21)$$

where $\mathbb{1}_4$ is the 4-dimensional identity operator, $u = \langle \sigma_j^x \rangle = \langle \tau_j^x \rangle$, and $v = \langle \sigma_j^x \tau_j^x \rangle$. By rewriting Eq. (21) in terms of the link variables given by Eq. (3) we obtain

$$\rho_j^{AT} = \frac{1}{4} (\mathbb{1}_4 + u \eta_{2j-1} + u \gamma_{2j-1} + v \eta_{2j-1} \gamma_{2j-1}), \quad (22)$$

with $u = \langle \eta_{2j-1} \rangle = \langle \gamma_{2j-1} \rangle$ and $v = \langle \eta_{2j-1} \gamma_{2j-1} \rangle$. Now, let us turn to the XXZ chain, whose two-spin reduced density operator reads

$$\rho_{j,j+1}^{XXZ} = \frac{1}{4} (\mathbb{1}_4 + p \sigma_j^x \sigma_{j+1}^x + p \sigma_j^y \sigma_{j+1}^y + q \sigma_j^z \sigma_{j+1}^z), \quad (23)$$

where $p = \langle \sigma_j^x \sigma_{j+1}^x \rangle = \langle \sigma_j^y \sigma_{j+1}^y \rangle$, and $q = \langle \sigma_j^z \sigma_{j+1}^z \rangle$. In terms of the link variables given by Eq. (11), we obtain

$$\rho_j^{XXZ} = \frac{1}{4} (\mathbb{1}_4 + p \eta_{2j-1} + p \gamma_{2j-1} - q \eta_{2j-1} \gamma_{2j-1}), \quad (24)$$

with $p = \langle \eta_{2j-1} \rangle = \langle \gamma_{2j-1} \rangle$ and $q = -\langle \eta_{2j-1} \gamma_{2j-1} \rangle$. Hence, since $u = p$ and $v = -q$, we have that Eq. (22) is equivalent to Eq. (24). Therefore, the eigenvalues of ρ_j^{AT} are identical to the eigenvalues of $\rho_{j,j+1}^{XXZ}$, which means that the von Neumann entropy are the same in both cases.
